Abstract

Land serves as a vital production resource, and therefore, land planning plays an important role in sustainable land-use design. Increasing the global population alters landscapes via land-use and land-cover change across different landscapes, including the drylands. Iran includes large areas of dryland, where the population increased by 60% from 1985 to 2016. Further population increase in Iran would require more land resources to be allocated for human needs. However, the pace and patterns of these changes remain unclear. The aim of this study was to map land-cover change from 1985 to 2016 and predict future land-cover change in the Zayandehrood ecologic sub-basins of Central Iran. By using multiseasonal Landsat imagery, nine thematic classes were mapped with a random forest classifier for 1985, 1998, and 2016 with an overall accuracy of 80% for each period. Classification results revealed that from 1985 to 2016 residential areas doubled and industrial areas increased at the expense of rangelands. Our study also revealed cropland expansion at the expense of rangelands, cropland abandonment and contraction of croplands due to residential and industrial development. Prediction of changes by 2036 with a multi-layer perceptron neural network and Markov chain analysis revealed further expansion of industries and residencies particularly nearby the protected areas such as Ghamashlu Wildlife Refuge. Predicted contraction of some degraded agricultural lands and concomitant agricultural expansion in the agricultural frontier by 2036, underscore the importance of sustainable land management in highly arid areas of Iran and improvement of the strategies for the protection of rangelands.

Abstract

Land serves as a vital production resource, and therefore, land planning plays an important role in sustainable land-use design. Increasing the global population alters landscapes via land-use and land-cover change across different landscapes, including the drylands. Iran includes large areas of dryland, where the population

increased by 60% from 1985 to 2016. Further population increase in Iran would require more land resources to be allocated for human needs. However, the pace and patterns of these changes remain unclear. The aim of this study was to map land-cover change from 1985 to 2016 and predict future land-cover change in the Zayandehrood ecologic sub-basins of Central Iran. By using multiseasonal Landsat imagery, nine thematic classes were mapped with a random forest classifier for 1985, 1998, and 2016 with an overall accuracy of 80% for each period. Classification results revealed that from 1985 to 2016 residential areas doubled and industrial areas increased at the expense of rangelands. Our study also revealed cropland expansion at the expense of rangelands, cropland abandonment and contraction of croplands due to residential and industrial development. Prediction of changes by 2036 with a multi-layer perceptron neural network and Markov chain analysis revealed further expansion of industries and residencies particularly nearby the protected areas such as Ghamashlu Wildlife Refuge. Predicted contraction of some degraded agricultural lands and concomitant agricultural expansion in the agricultural frontier by 2036, underscore the importance of sustainable land management in highly arid areas of Iran and improvement of the strategies for the protection of rangelands.

Introduction

Land serves as a vital production resource and therefore land planning plays an important role in sustainable land use design (Foley *et al.* , 2011; Lambin & Meyfroidt, 2011). Human-induced land-use and land-cover change (LULCC) are the key proximate causes that shape landscapes at different scales (Foley, 2005; Lambin & Geist, 2006). Evidence shows that LULCC increased over the last 100 years due to population growth, and subsequent increasing land demand and changing consumption patterns, among other factors (Gerbens-Leenes & Nonhebel, 2005; Goldewijk, 2001). It is envisaged that the purpose of land planning is to direct the agents that change land use (e.g., landowners, farmers) to a point that results in the balance between meeting societal needs and protection of the environment. Hence, the quantitative assessment of the state of land cover and land use and revealing the potential changes of land cover is crucial for better sustainable land-use planning (Herrmann & Osinski, 1999).

Earth observation, such as satellite remote sensing, is a prominent approach to monitor land changes and produce land-cover maps (Cohen & Goward, 2004; Coppin *et al.* , 2004; Hansen & Loveland, 2012). There has been substantive progress over the last three decades with the aid of remote sensing to monitor how humans appropriate land; for instance, the dynamic of residential and industrial areas (Reba & Seto, 2020), agriculture and forestry activities (Eisavi *et al.* , 2015; Hansen *et al.* , 2013; Rufin *et al.* , 2019), and also the intensity of appropriation of rangelands (Dara *et al.* , 2020; Jakimow *et al.* , 2018), including drylands (Dubovyk, 2017). In the past, scientists have relied on field surveys and interpretation of aerial photographs to map LULCC, often over smaller areas (Nebiker *et al.* , 2014). As the size of the area of study becomes bigger, field surveys and interpretation of aerial photos become very costly and time-consuming. Therefore, satellite remote sensing is an excellent source of information to study LULCC at local and regional scales because satellite images, from on-board of Landsat satellites for instance, can cover a large extent and have a higher temporal coverage compared to field based observations and aerial surveys (Hansen & Loveland, 2012; Loveland & Dwyer, 2012). Landsat images from the freely accessible United States Geological Survey (U.S.G.S.) archive are used widely to evaluate the quantitative parameters of land, especially land use/cover change due to long historical repetitive coverage, the spatial resolution of Landsat images that match LULCC phenomena and relevant radiometric resolution suited to map vegetation change, including drylands and rangelands (Eisavi *et al.* , 2015; Ridwan *et al.* , 2018; Roy *et al.* , 2014). Moreover, the change of paradigm about free accessibility of Landsat records made this data relevant for the scientific community to monitor LULCC (Wulder *et al.* , 2012).

There has also been progress in the application of semi-automatic classification methods to derive thematic classes from satellite imagery and produce LULCC maps. Machine-learning algorithms gained popularity recently to classify satellite imagery due to the ability to handle non-linearity among spectrally complex classes, such as various urban landscapes, agriculture and rangelands (Dara *et al.* , 2020; Khatami *et al.* , 2016; Kraemer *et al.* , 2015; Löw *et al.* , 2015). Random forest, which is probably the most popular machine-learning classification method, is an ensemble classifier, where, instead of one single tree (CART and C4.5),

multiple trees from training data are produced. Such an approach allows the model overfit to be reduced (Belgiu & Drăguț, 2016; Gislason *et al.*, 2006). At the same, compared to CART no pruning of produced trees is implemented in a random forest, which allows increasing classification accuracy with random forest (Belgiu & Drăguț, 2016; Gislason *et al.*, 2006). High precision, ability to learn nonlinear relationships, ability to determine variables, non-parametric nature, high computation speed, and resistance to over-fitting are among the advantages of random forest classifier (Belgiu & Drăguț, 2016; Gislason *et al.*, 2006; Millard & Richardson, 2015). It has been also noted, classification error decreases by increasing the number of trees; both the number of trees and the number of utilized variables for branches of each node can be parameterized (Belgiu & Drăguț, 2016; Gislason *et al.*, 2006). The random forest classifier has been widely used over the last two decades for land-change mapping (Chen *et al.*, 2019; Jakimow *et al.*, 2018; Millard & Richardson, 2015). In sum, a random forest classifier can be a promising classifier to map LULCC in spectrally complex areas, such as the drylands of Iran (Eisavi *et al.*, 2015).

Various models have been used for investigating the dynamics of land use and predicting the land-use changes in order to improve decision-making (Castella & Verburg, 2007; Verburg *et al.*, 2006; Zhang *et al.*, 2015). Some models, especially dynamic models such as Markov, dynamic systems, automatic cells, multi-agent models, and conversion of land use and its effects at small regional extent (CLUE-S), can help the decision-makers to evaluate potential land-cover change patterns under the different scenarios (Mallampalli *et al.*, 2016; Sun *et al.*, 2016; Verburg *et al.*, 2002). Each of these models has advantages and disadvantages for predicting land-cover change. For instance, geometry modification technology (GEOMOD) can model only two land-cover change classes (Pontius Jr & Chen, 2006) and SLEUTH (slope, land use, exclusion, urban extent, transportation and hillshade) is primarily used for urban development and cannot capture the driving forces behind urban growth. Additionally, SLEUTH has limitations on the number of input variables and can be implemented only under the UNIX system (Chaudhuri & Clarke, 2013; Sekovski *et al.*, 2015). SLEUTH is deliberately focused more on form and dynamics, i.e., “where” could the development take place, but not “why” (e.g., demography and socioeconomic processes) (Sekovski *et al.*, 2015).

Land Change Modeler, available via Terrset software (former Idrisi software, Clark Labs) (Eastman, 2015), can model multiple land-cover change trajectories simultaneously in comparison to the above methods and tools. One of its advantages is that it is available via Terrset and can be run with Windows operating system, therefore it is more available for a broader community. It has no limitation on the number of input variables. It provides more capabilities for tuning than other methods, in addition to its simplicity. Land Change Modeler has been used to evaluate and model various land-cover changes in Iran (Ansari & Golabi, 2019).

Unsustainable land-use activities may result in substantial negative ecological consequences with cascade effects even when land-use change occurs at the local level (Newbold *et al.*, 2015; Yaghobi *et al.*, 2019). Reduction of the negative environmental impacts of land-use change while maintaining economic viability and social acceptability is a particular challenge for most developing countries in Asia, including Iran (Zhao *et al.*, 2006). For instance, in Iran, the population increased by 60% from 50 million to 80 million people just within a 30-year course from 1986 to 2016 (Danaei *et al.*, 2019). Over the same course, the urban population increased and by 2016, it comprised 70% (Danaei *et al.*, 2019). Most of the territory of Iran can be considered dryland with vast rangelands and irrigated croplands lying in semi-desert conditions (Mesgaran *et al.*, 2017; *The Cambridge History of Iran*, 1968). There has been documented evidence of environmental degradation caused by unsustainable urban and agricultural expansion (Minaei *et al.*, 2018; Yaghobi *et al.*, 2019; Zareie *et al.*, 2016). This all increased the concern of the scientific community on the negative impact on the environment and the relevance of quantification and prediction of such impacts.

The ultimate goal of this study was to assess land-cover change with the aid of multiseasonal Landsat satellite imagery from 1985 to 2016 in Zayandehrood ecologic sub-basins of Central Iran, an area of rapid agricultural and urban/industrial development and to determine the required land amount for various land uses in the future. Our specific research questions were:

1. What are the major trajectories of land-cover change in Zayandehrood ecologic sub-basins of Central

Iran from 1985 to 2016?

2. What will be the future land-cover/ use transitions in the study area by 2036?

Methods

2.1 Study area

The study area includes the three sub-basins of Zayandehrood: Lanjanat, Najafabad, and Mahyar Shomali, which are located at 50° 57' to 51° 51' of eastern longitude and 31° 45' to 32° 50' of northern latitude with an area of 527,148 hectares in the Isfahan province of Iran (figure 1).

The population in the study area increased from 321,000 in 1996 to 2.26 million people in 2016 (<https://www.isfahan.irib.ir>). The climate ranges from arid and semi-arid (east and southeast) to cold semi-humid (west and southwest) with an elevation range from 1,569 m (plains, hills) to 3,235 m (mountains). Rainfall increases with elevation, while temperature decreases. The mean annual temperature is 13 °C, and the mean annual rainfall is 209 mm. The Zayandehrood River is the biggest and most important river in the study site, which originates in the Zagros Mountains (figure 1). This river provides water for farming, residential areas and industries in the study site and finally goes to the Gavkhoni wetland in the east of the watershed (Akbari *et al.* , 2015; Iranmehr *et al.* , 2015). The Ghamashlu National Park in the north and Kola Ghazi National Park in the Southeast host charismatic herbivores, *Capra aegagrus* and *Gazella subgutturosa* . Among protected native plants in the study area are *Fritillaria imperialis* and *Pistacia atlantica* . Therefore, despite semi-arid conditions, the study area has high biodiversity and importance for environmental protection. Different land uses, such as residential areas, agriculture, industries and mining, emphasize the importance of obtaining accurate information about the state of land use and of developing strategies for sustainable land use in the future.

<Figure 1>

2.2 Data

In this study, U.S.G.S. Landsat multiseasonal imagery for the years circa 1985, 1998, and 2016 were used to match the development of land-planning policy over the last decades in Iran. Landsat images are well-suited to distinguish different land-cover types due to the spectral and spatial resolution of the sensors (TM, ETM+, OLI) on board Landsat satellites, and also due to the temporal revisits. To determine different phenological stages of spring and summer crops, image-dates for May and August were selected. Systematically corrected (topography and atmosphere) level 2 Landsat imagery from TM and OLI sensors were acquired from U.S.G.S. for World Reference System -2 (WRS-2) path 37 and 38 and row 164. We then mosaicked satellite imagery from different paths.

2.3 Classification with random forest classifier

Image classification is a method for extracting environmental parameters, such as land cover and land use (LCLU) (Jensen, 2004). An expert who conducts a supervised classification should have prior knowledge about study area conditions and land uses. For this study, training samples were determined by using available maps, aerial images, field data and ancillary spatial information, such as soil types. We used a random forest classifier implemented in the package “random Forest” in statistical R software. Based on the literature and preliminary tests, we used 1,000 trees to parameterize the random forest classifier. We used the Blue, Green, Red, NIR, SWIR-1, and SWIR-2 bands for Landsat 4, 5 TM, Landsat 7 ETM+ and Landsat 8 OLI to produce LCLU change maps with a random forest classifier. The iterative classification approach was used with an increase of training samples selected for each thematic class until the classification accuracy for individual thematic classes did not increase anymore.

We developed a classification catalog, which presented a mix of LCLU classes (Table 1). Our classification catalog consisted of eight thematic classes: ‘forest’, ‘agriculture’, ‘rangeland’, ‘water’, ‘rocks’, ‘industry’, ‘residences’, and ‘other’. The ‘forest’ class consisted of urban and industrial green space with trees and tree plantations, ‘agriculture’ consisted of tilled agricultural land used for crops and clean or green fallow land as

a part of crop rotation. The ‘rangeland’ class consisted of native natural plants with low (type I) to medium (type II) density. ‘Water’ represented water objects, such as rivers, natural wetlands and man-made water ponds. The ‘rock’ class consisted of rocky outcrops and the mountains. ‘Industry’ consisted of industrial areas and mines. ‘residences’ comprised urban and rural settlements and main paved roads and the ‘other’ class was bare soil, industrial and mineral wastelands, and dirt roads.

<Table 1>

2.4 Field data collection for parameterization of the classifier and accuracy assessment

Field data, which was later utilized for training and accuracy assessment, was collected following several steps. Field campaigns were conducted and information about land-cover types was recorded with a non-differential GPS during May and August 2016. Notes were also taken on land-cover and land-use types. For a better interpretation of the results, photos were taken in the field as well. We also interviewed the farmers about their activities to reconstruct land use by recalling memories about land use, back to 1985. Field-collected data were then used to parameterize and correct the random forest classifier, and assess the classification accuracy of produced maps. We showed satellite imagery available via Google Earth mapping services during the interviews with farmers if we were not sure about the type of LCLU.

2.5 Post-classification change detection

The process of LCLU change determination is attributed to change detection over time (Coppin *et al.* , 2004; Lu *et al.* , 2004). A post-classification change detection approach was used to assess land transitions from 1985 to 1998 and 2016. More specifically, five trajectories were assessed in more detail: “rangeland to residences”, “rangeland to forest”, “agriculture to residences”, “rangeland to agriculture”, and “rangeland to industry”.

2.6 Accuracy assessment of classified land-cover/ use maps

The accuracy of produced maps was examined quantitatively with validation data produced by visual expert interpretation of multiseasonal Landsat imagery, high-resolution satellite imagery available via Google Earth™ mapping service and the use of field-collected data. Accuracy assessment was performed for 1985, 1998 and 2016 maps. In total, 1,277 points were used to evaluate the accuracy of the thematic maps, which were produced with a stratified random sampling approach. Overall, producer’s and user’s accuracies were calculated based on contingency tables between validation data and classified maps.

2.7 Prediction of land cover/ use change

Land cover/ use change can be determined by biophysical, technological, economic, social and political drivers but also by trigger events (Bürgiet *et al.* , 2004; Geist & Lambin, 2002; Hersperger *et al.* , 2010). Here we used biophysical site conditions to predict the spatial characteristics of LCLU change from 1985 to 2016 with the Terrset Land Change Modeler, where we developed several sub-models. Based on potential transition scenarios, following “business-as-usual” namely, rangeland to other land uses and agriculture to residences, time-dependent (dynamic) and time-independent (static) descriptive variables were determined in order to assess the transition potentials of pixels of one land use/cover to another (De Rosa *et al.* , 2016). Cramer coefficient, which ranges from “0” (no correlation) to “1” (strong correlation), was used to determine the correlation of model variables (independent variables) with LCLU classes (dependent variables). The prediction of LCLU transition was made separately for five transition classes, namely “rangeland to residences”, “rangeland to forest”, “agriculture to residences”, “rangeland to agriculture”, and “rangeland to industry”. LCLU change was predicted for 2016 and 2036 with a multi-layer perceptron (MLP) neural network. To determine the amount of change that will occur up to 2036, we used the Markov chain prediction process.

Several spatial biophysical and socioeconomic variables, namely, distance to water, residences, industries, agriculture and rangelands (based on classification results for 1985 and 2016), slope, distance to roads and flood potential, determined the likelihood of LCLU change transitions (figure 6). The slope was calculated based on a 30-meter shuttle radar topography mission (SRTM) digital elevation model (DEM) (figure 6). The

Euclidian distance to roads was calculated based on the digital map of main roads. Similarly, the Euclidian distance to water was calculated with the account of the Zayandehrood River and the main water channels. We also assessed the susceptibility to floods (flood potential), which was determined based on the calculation of the distances to seasonal and permanent water flows based on hydrologic maps for the study area. All produced maps were calculated with a 30-meter pixel size to match the LULCC maps.

Results

3.1 Land use/cover classification and accuracy assessment

Our classified land-cover maps for 1985, 1998, and 2016 consisted of ‘rocks’, ‘rangeland type I’, ‘rangeland type II’, ‘water’, ‘agriculture’, ‘residences’, ‘forest’, ‘industry’ and ‘other’ thematic classes, and were produced with plausible classification accuracies (figure 2, Table 2). To increase the accuracy for the ‘agriculture’ class, lands with clean and green fallow, tilled soil and lands under crops were combined. To increase the accuracy of the ‘residences’ class, post-classification assessment was performed with a reverse comparison of the residences’ patterns; if they first appeared in 1985, they should also appear in the 1998 and 2016 maps (the assumption being that there was no reduction in residential area over time).

<Figure 2>

Table 2 shows the accuracy of maps and classes produced with a random forest classifier. The ‘agriculture’ thematic class had a high accuracy in all years. The accuracies for the ‘rangeland type I’, and ‘forest’ thematic classes were high as well. The user’s and producer’s accuracies for the ‘residences’ class varied from 0.67 to 0.80. The classes ‘rocks’, ‘other’, and ‘rangeland type I’ were the least accurate ones due to low spectral separability among these classes.

<Table 2>

3.2 Land use/cover change detection

Results showed that the ‘water’ and ‘rocks’ thematic classes had a negligible decrease during the studied period. The ‘water’ thematic class, which included rivers, water channels and big man-made pools, might exhibit inter-annual change due to fluctuation of precipitation levels for the three studied periods (figure 3). The presence of snow in one of the images for 1998 could affect the extent of the ‘rangeland type II’ thematic class. ‘Industry’, ‘forest’, ‘residences’ and ‘agriculture’ thematic classes increased from 1985 to 2016, while the ‘rangeland type I’ thematic class steadily decreased (figure 4). From 1985 to 2016, the ‘forest’ thematic class increased ten times, the ‘industry’ thematic class three times, and the ‘residences’ class two times.

<Figure 3>

<Figure 4>

A detailed visual inspection of classified maps revealed that the ‘agriculture’ thematic class expanded mostly at the expense of the ‘rangeland type I’ thematic class, with 3.3% growth in area from 1985 to 2016 (table 2, table 3). Visual qualitative inspection of land use/cover change also revealed forests and urban greenery that had been planted mainly around the industries and mines from 1985 to 2016 (figure 5). Spatial growth of residential areas from 1985 to 2016 primarily occurred at the expense of agricultural lands, ‘rangeland type I’, and in close proximity to existing residential areas and roads (figure 5).

<Table 3>

<Figure 5>

Results also showed that the conversion of ‘agriculture’ to ‘residences’ and ‘forest’ was more pronounced from 1998 to 2016 than from 1985 to 1998, which was different for the transition from ‘rangeland type I’ to ‘industry’ (which dominated from 1985 to 1998).

3.3 Land-cover/ use change prediction

By using the VALIDATE method in the Terrset GIS software, agreement was measured between predicted maps and the classified map for 2016. The Standard Kappa Index, Quality Kappa Index (no location), and Location Kappa Index for 2016 model validation were 0.91, 0.92, and 0.93, respectively (table 4). The accuracy of the predicted map for 2016 was 88%.

The predicted LULCC map from 2016 to 2036 revealed multiple trajectories of land transformation, such as an increase of some classes often at the expense of rangeland type I. For instance, ‘residences’ should increase to 9000 (ha) at the expense of class ‘agriculture’ and ‘rangeland type I’ (figure 7, 8).

<Table 4>

<Figure 6>

<Figure 7>

<Figure 8>

Discussion

Land-cover/use change has various implications for the environment (De Rosa *et al.*, 2016). LULCC prediction models provide the possibility to assess the change of land cover and land use and supply important information for better land-use planning to managers and stakeholders (Ansari & Golabi, 2019; Herrmann & Osinski, 1999). Often, watersheds are considered as an important assessment unit for land planning. Therefore, we determined our study area based on the ecologic border of the Lenjan and Najafabad watersheds of the Zayandehrood River to prepare a suitable estimation of the spatial transition potential of the land. The study area is within the province administrative units and the results of the study can be used for the development of land management plans.

We reconstructed land cover/ use change with multiseasonal Landsat imagery for 1985, 1998 and 2016 for the watershed surrounding the Zayandehrood River, which is the main water resource of the study area and our study revealed multiple trajectories of land change. For instance, our study showed both agricultural expansion, but also abandonment (an increase of fallow and completely abandoned areas from 1985 to 2016). Several studies suggested that human factors, such as over-using underground water resources, and water transfer plans are the main reasons for water decrease including the Zayandehrood River and, consequently, resulting in abandonment of agriculture plots where irrigation and production costs on degraded lands are not compensated by the returns from farming (Azadi *et al.*, 2016; Fazli, A & Badi, Sh, 2017; Minaei *et al.*, 2018). Therefore, the current water management plans are not sustainable as they result in exhausting water resources and salinization of some plots as in other parts of Iran (Iranmehr *et al.*, 2015; Yaghobi *et al.*, 2019; Zeaiean *et al.*, 2005).

Our classification results also revealed the conversion of agricultural lands to residences and recreational and industrial areas in close proximity to residential areas, in drought-prone areas, and with deficient water resources. These findings were in line with earlier studies in other parts of Iran, which also found a contraction of agricultural lands in proximity to residential areas (Eisavi *et al.*, 2015; Mosammam *et al.*, 2017; Soffianian & Madanian, 2015). Such finds are worrisome because Iran also relies on food imports. Any additional contractions of croplands in Iran may pose a threat for food insecurity.

Our findings also showed that residential areas and even new industrial towns such as Majlesi were built at the expense of the rangelands. Contrary to the contraction of agricultural lands in the vicinity of residential areas, we also observed an increase in agricultural land at the expense of rangelands. Rangelands that were not converted to croplands, were often left at the marginal areas. Thus, any new cropland expansion at the expense of rangelands suggested cropland encroachments in agro-environmental frontiers with unstable yields and in areas prone to abandonment (Kraemer *et al.*, 2015; Yaghobi *et al.*, 2019). Rangelands in many parts of the world, including Iran, have a weak protective status. At the same time, rangelands host charismatic umbrella species and support the livelihoods in rural areas, including rangeland livestock herding (Behnke *et al.*, 2016; Dara *et al.*, 2020; Kerven *et al.*, 2006). Therefore, the permanent conversion of rangelands

to industrial areas should be controlled, and zoning should be developed to avoid the unintended land conversions and reduction of valuable ecosystem services rangelands provide (Gudka *et al.* , 2014; Kamp *et al.* , 2015). With the current land management policies and prediction of land-change we provide, the protected areas, especially Ghamashlu Wildlife Refuge, in our study area (figure 8) are at risk. For instance, our study revealed ongoing residential expansion in proximity to the Wildlife Refuge.

The presence of mineral sources in our study area, particularly in the mountains, resulted in the expansion of opened-cast mining, thus creating conflicts with environmental preservation strategies. Our land-change predictions and evaluation of existing plans about mining suggest further continuation of the negative impact of mining and supplementary road construction on rangelands and other drylands (Madadi *et al.* , 2014; Makki *et al.* , 2012). Expansion of big industrial towns and various mines over the last 30 years has also intervened between natural resource management and exploitation of water resources with other land uses such as farming (Soffianian & Madanian, 2015). Given a shortage of water resources in the study region of Iran, a vicious circle between the expansion of various land-use practices and water resources may result in further contraction of valuable land resources, and therefore, our results are extremely relevant for better land-use planning in the drylands of Iran.

In this study, we evaluated land-cover changes starting from 1985 to 2016. Land-change transformations started much earlier than our first year of observation (1985), for instance following the change of the political and institutional course in Iran in 1978. However, we captured an overall course of post-1978 land-cover change driven by the aim of satisfying the needs of the growing population. Before 1985, Landsat satellite imagery were scattered (Landsat 4 and 5 TM) or came with coarser spatial and radiometric resolution (Landsat 1-3 MSS). Similarly, we made projections about land-cover change by 2036 based on the overall course of land transformation in the past, therefore reflecting the "business-as-usual" scenario. There might be other counterfactual scenarios that may mediate the rates and patterns of land-cover change, such as adjustment of existing land-use policies (Mallampalli *et al.* , 2016; Prishchepov *et al.* , 2019), change of economic conditions in Iran, etc. However, our projection can be used as a starting point of evaluation of existing policies and additional counterfactual scenarios can be built around.

Our study showed multiple pathways of land transformations in the dryland of central Iran, for instance, when both cropland expansion and abandonment concomitantly are taking place and go hand in hand with urban sprawl at the expense of rangelands. Despite the extreme climatic conditions, global drylands, which occupy almost half of the global surface (Právělie, 2016), are experiencing rapid land transformation due to the overall population increase. Moreover, a large portion of drylands are in developing countries, such as Iran, where livelihoods strongly depend on agriculture and environmental goods (Brandt *et al.* , 2017; Emg, 2011; Tong *et al.* , 2017). Despite a growing population across dryland, both cropland expansion and abandonment have also been found in other parts of the drylands of Northern Eurasia, such as Kazakhstan (Chen *et al.* , 2013; Horion *et al.* , 2016; Löwet *et al.* , 2015), Mongolia (Dong *et al.* , 2011; Jamsranjav *et al.* , 2018; Sankey *et al.* , 2018) and Uzbekistan (Dubovyket *et al.* , 2012). Considering the adverse climatic projections that drylands of Eurasia will face during the 21st century (Groisman *et al.* , 2017; Groisman & Soja, 2009), better land-use policies should be developed toward sustainable use of land and water resources to satisfy predicted population growth.

Table 1: Thematic land-cover and land-use classes.

Class	Short description
Rocks	Rocky outcrops
Rangeland type I	Rangelands with low-density vegetation
Rangeland type II	Rangelands with moderate density vegetation
Water	Rivers, artificial ponds, wetlands and water channels.
Agriculture	Agricultural land used for crops, orchards
Forest	Forest, urban and industrial green areas (e.g., parks)
Residences	Urban and rural settlements and paved roads
Industry	Industrial areas and mines
Others	Industrial and mineral wastelands, dirt roads, bare soil

Table 2: Accuracy and extent of land use/cover classes (in hectares)

	1985	1985	1985	1985	1985	1998	1998	1998	1998	1998
