Key Points:

- Preexisting weaknesses in the CSZ amplify postglacial horizontal stresses and cause large clockwise stress rotations
- Stress rotation is further amplified in mid-crust due to low friction and semi-brittle behavior
- The frequency-magnitude distribution of earthquakes suggests an inverse relationship of *b*-value with differential stress in the upper crust

Abstract

Intraplate tectonic stress fields are complex due to the imprint of a long geological history. Here we use a new dataset of earthquake focal mechanism solutions and relocated events to investigate the relationship between regional stress, crustal strength, and seismicity in the Charlevoix Seismic Zone (CSZ), the most active seismic zone in eastern Canada. Our stress inversion shows that S_{Hmax} gradually rotates clockwise from approximately St. Lawrence River-parallel near the surface to river-perpendicular in the lower crust, as postglacial rebound stress becomes increasingly dominant at greater depth. The stress rotation occurs primarily between ~13 and ~26 km depth, where glacial rebound induced stress perturbation is further amplified by a “weaker” middle crust of an estimated apparent friction coefficient of ~0.5. Finally, depth-dependent *b*-values confirm the rheological difference between upper and middle crust in the CSZ.

Plain Language Summary

The occurrence of earthquakes in continent interiors is controlled by several geological and geophysical conditions which are often poorly known. High-resolution earthquake catalogs and information about faulting mechanisms are therefore key for recognizing and quantifying the crustal stress and strength conditions in these challenging regions. This study focuses on the Charlevoix Seismic Zone (CSZ), one of the most seismically active regions in eastern North America. By analyzing a new set of earthquake distribution and faulting data, we found that the combination between a “weak” fault zone and crustal stresses generated by postglacial rebound possibly controls the spatio-temporal distribution of earthquakes in the CSZ. In particular, the seismicity rate and faulting style in the CSZ strongly relate with the depth-dependent frictional and rheological properties of the crust.

1. Introduction

Crustal stress magnitude and orientation exhibits primary control on fault slip and earthquake rupture behavior. Because direct *in situ* stresses measurements are challenging and often restricted to the shallowest part of the upper crust, regional stress field orientation is typically inferred by indirect estimation, particularly at seismogenic depths. Stress inversion based on earthquake focal mechanism solutions (FMS) provide a robust tool to quantify the spatio-temporal distribution of stress orientation and relative magnitudes that are critical for studying the source mechanisms of plate boundary and intraplate seismicity (e.g., Hardebeck & Hauksson, 2001; Mazzotti & Townend, 2010). Moreover, results from stress inversions can be evaluated against the frequency-magnitude distribution of earthquakes to better understand the relationship between seismic activity, stress orientation, and crustal strength (Abolfathian et al., 2019). For example, *b*-values exhibit spatio-temporal variations that may be indicative of spatio-temporal changes in stress. Van Stiphout et al. (2009) found that higher *b*-value is associated with slab dehydration in the Alaskan subduction zone, which leads to pore pressure increases and subsequent fault strength reduction that promotes failure. Mori & Abercrombie (1997) studied the influence of earthquake hypocenters between 0 and 13 km from various dataset (**M** 2.0 - 5.5) in northern and southern in California, and found that decreasing heterogeneity in crustal materials with depth leads to *b*-value decreases. They interpreted rupture growth increases with lithostatic stress and decreasing heterogeneity to lead to an increase in propensity of larger earthquakes with depth as the crust becomes more homogeneous.

Intraplate tectonic settings pose specific challenges for quantifying crustal stress and strength conditions and their relation to earthquakes. In general, the relatively lower intraplate seismicity rates provide limited information about the geological and geophysical conditions for generating earthquakes, such as well-constrained earthquake rates or potential maximum magnitudes, which are key parameters for hazard assessment (Stein & Mazzotti, 2007 and references therein). Nevertheless, intraplate settings can experience infrequent, destructive earthquakes. The

Charlevoix Seismic Zone (CSZ) (Figure 1) along the St. Lawrence paleorift system in eastern Canada is one of the most seismically active intraplate settings, and has experienced five **M** 6+ earthquakes since the seventeenth century (Adams & Basham, 1991; Lamontagne, 1987), including a **M** 7.3 to 7.9 in Charlevoix in 1663 (Ebel, 2011). Structural inheritance related to the Grenville and Taconian orogeny, the coincident breakup of Rodinia and opening of the Iapetus Ocean, and late Ordovician to early Silurian meteorite impact causes extensive lithospheric-scale tectonic weakness within the paleorift system (Lemieux et al., 2003; Mazzotti & Gueydan, 2018; Rondot, 1971; Schmieder et al., 2019). The rifting associated with the Iapetus Ocean opening created the St. Lawrence valley system of normal faults that are presently under compressional stress conditions (Adams & Basham, 1991; Johnston, 1989). Seismic tomography and gravitational field modeling suggest that seismic velocity variations are dominated by the distribution of crustal fractures within the impact structure and material composition outside the impact structure. The crustal characteristics dictate distinctive spatial distributions of earthquake source properties, such as magnitudes, focal mechanisms, and static stress drop values (Onwuemeka et al., 2018; 2021). Postglacial rebound associated with glacial retreat following the Wisconsin glaciation (85 – 11 kyr) superimposes ambient stresses which possibly contribute to stress perturbations on critically stressed faults in the CSZ (Quinlan, 1984; Wu & Hasegawa, 1996). In particular, Mazzotti & Townend (2010) hypothesize that postglacial rebound in combination with a weak fault zone may explain the ~30° clockwise rotation of the maximum horizontal stress from shallow borehole measurements to those inferred from CSZ earthquake FM solutions. While the FMS-inferred stress orientations by Mazzotti & Townend (2010) may be representative of the entire region, the limited number of solutions (60) from their study make it difficult to estimate possible spatial variation of the stress orientation. In particular, depth-dependent stress variation would provide critical insights for understanding the rheological properties of the lithosphere, fault structures, and their influence on earthquake source processes, as demonstrated in other regional studies (Bokelmann & Beroza, 2000; Li et al., 2018).

In this study we take advantage of a new catalog of 161 FMS (**M** 1.5+) calculated using a full-waveform moment tensor inversion technique to investigate the spatial variations in stress field orientation with respect to the earthquake distribution in the CSZ. We combine FMS with existing data to determine the orientation and relative magnitudes of the principal stresses with particular focus on depth-dependent variations. We show the maximum horizontal stress rotates clockwise with depth from the near surface approximately river-parallel borehole breakout orientation toward roughly river-perpendicular maximum strain rate direction inferred in the lower crust. The stress rotation occurs primarily in the middle crust (~13-26 km), where the effect of postglacial rebound is amplified by a "weaker" crust with low frictional strength and semi-brittle rheology.

2. Data and Methods

We use a dataset of 1760 earthquakes (M_N -0.7 – 5.4; M_N is Nuttli magnitude (Nuttli, 1973)) that occurred in the CSZ between January 1988 and August 2017 (Figure 1a), with a ~ 2 years gap between 2010 and 2012 built from combining the relocated earthquake catalogs of Yu et al. (2016a) and Onwuemeka et al. (2018). We calculate the *b*-value and the magnitude of completeness (M_c) of the relocated catalog using the maximum likelihood method (Utsu, 1965) and Goodness-of-Fit test (Wiemer & Wyss, 2000), respectively, using the mean values of 1000 bootstrap runs and the 68% confidence intervals.

We apply the probabilistic earthquake source inversion framework *Grond* (Heimann et al., 2018) to perform full moment tensor inversion of 161 M 1.3+ events reported between April 2000 and February 2018. We use waveform data recorded by seven CNSN stations (CN network, operational since October 1994), six Quebec-Maine Transect campaign stations (X8 network, August 2012-August 2016), two USArray Transportable Array campaign stations (TA network, August 2013-July 2015;), and four temporary McGill University stations (MG network, since July 2015) in the Charlevoix area. Following Onwuemeka et al. (2018), we use the St. Lawrence River south shore velocity model of Lamontagne (1999) to precalculate Green's Functions (GF) for modeling synthetic seismograms. Text S1 details the moment tensor inversion. We augment our solutions with 64 additional FMS (63 FMS of events occurring between June 1974 and October 1997 and 1 FMS of the 1925 M 6.2 Charlevoix – Kamouraska event) of varying quality factors (27 A, 11 B, 24 C, and 2 D; quality factor decreases alphabetically) computed by Mazzotti & Townend (2010). We then use the combined 225 FM (Figure 1b) to invert for the principal stress orientations, stress ratio $R = (\sigma_1 - \sigma_2)/ (\sigma_1 - \sigma_3)$, and apparent friction coefficient (μ) through an iterative joint focal mechanism inversion (STRESSINVERSE, Vavryčuk, 2014). Following Abolfathian et al. (2019) we refer to μ as the apparent friction coefficient, which is calculated in the stress inversion procedure. A bootstrap resampling (500) of the original set of 225 FMS constrains the 95% confidence intervals. In addition, we determine the orientation of the maximum horizontal stress, S_{Hmax}, with the method of Lund & Townend (2007). Text S2 details the standard stress inversion procedure.

3. Results

3.1 Spatial variability of b-value in the CSZ

The estimated M_c and *b*-value for the entire catalog are1.86 and 0.96 (0.92 – 0.99), respectively (Figure S1a). The 1432 events located within the impact structure have calculated M_c of 1.92 and b-values of 1.06 (1.02 – 1.09), while M_c and *b*-values of the 328 events located outside the impact structure are 1.54 and 0.70 (0.67 – 0.72), respectively (Figure S1b, c). To avoid bias in *b*-value estimation due to changes in M_c (Hainzl, 2016), we also calculate *b*-values using a fixed M_c equal to the one estimated for the entire catalog (1.86). The resulting values of 1.05 (1.03 – 1.07) for the events within the impact crater, and 0.78 (0.75 – 0.81) for events outside are in agreement with results from Yu et al., (2016a).

Furthermore, we compute the depth-dependent variation of M_c and *b*-value using 50% overlapping windows of 300 events (Figure 2). Depth-dependent changes in *b*-value and M_c appear to follow a similar trend (Figure 2b, c). In order to increase the estimate robustness, we recalculate *b*-values at a fixed M_c (1.86) for each depth interval (Figure 2d). Figure 2d shows results from both the entire catalog (black points and line), and events within the impact structure (magenta points and line). The *b*-values of the entire catalog clearly decrease with depth from ~ 1.1 to ~ 0.9 until approximately 12 km, followed by a brief rebound to ~ 1.0 for about 1 km, before returning to ~ 0.9 at greater depth. Events within the impact structure show *b*-values similar to the entire catalog until ~10 km depth, followed by a sudden increase with depth that peaks at ~1.2 at ~ 12.5 km. Between ~12.5 km and 15 km, *b*-values are similar between the two groups. Below ~15 km, the events within the impact zone exhibit higher *b*-values relative to the full catalog, although the estimates are less well-constrained due to the decrease of seismicity with depth (Figure 2a). The strong contrast in the *b*-value-depth variation between the two event populations likely results from the fact that seven of eight $M_N \geq 4$ earthquakes in the full catalog occurred outside the impact structure (Figure 2d), causing a strong statistical bias toward the larger magnitude events in the *b*-value estimate.

3.2 Focal mechanisms and moment tensor inversion

The majority of the earthquakes exhibit reverse-faulting kinematics (Figure 1b) consistent with reverse-sense reactivation of pre-existing Iapetus normal faults (e.g., Mazzotti & Townend, 2010; Onwuemeka et al., 2018). The extensive damage and relative higher fault/fracture density produced by the meteorite impact likely explain the higher diversity of FMS within the impact structure relative to other locations in the CSZ (Yu et al., 2016a).

Stress inversion results of the 225 FMs produce a maximum principal stress (σ_1) with a mean azimuth of 93° (Figure 1b), a roughly vertical minimum principal stress (σ_3), and intermediate principle stress (σ_2) with a mean azimuth of 184°. The estimated S_{Hmax} has a mean azimuth of 90.7°, which represents a clockwise rotation from the regional S_{Hmax} of 54° determined from borehole breakout studies (Mazzotti & Townend, 2010). Stress ratios *R* range between 0.26 and 0.56 with mean value of 0.41.

We evaluate the stress variation with depth by inverting for the principle-stress orientations in subset groups of 75 events overlapping by 60 events. We also invert for the maximum horizontal stress (S_{Hmax}), the stress ratio (R), and apparent friction coefficient (μ) within subsets (Figure 3). The results show a depth-dependent clockwise rotation of both σ_1 and σ_2 (Figure 3a, b). Mean values of σ_1 and σ_2 remain constant down to ~12.5 km within the 95% confidence intervals, with the largest stress rotation of σ_1 from azimuth ~ 80° to 110° and σ_2 from ~ 170° to 200° between ~12.5 and ~16 km depth. The inversion results show no additional stress rotation below ~16 km. In addition to the azimuth rotation of σ_1 and σ_2, the σ_1 plunge rotates from near-horizontal (~5°) to a shallow dip angle (~ 15°) at ~15 km depth (Figure 3c). Our results also show a decreasing trend with depth of both the *R* value from 0.7 at shallow depths to 0.25 at ~16 km and μ from 0.8 to 0.45 over the same depth range (Figure 3d, e). Finally, the results show a total clockwise rotation of S_{Hmax} of ~30° (82.5° to 111.8°) between shallow and deeper FMS (consistent with the σ_1 and σ_2 azimuthal rotations) and a total clockwise rotation of ~58° from the regional S_{Hmax} of 54° determined from borehole breakouts (Mazzotti & Townend, 2010) (Figure 3f).

4. Discussion

The S_{Hmax} orientation from borehole breakouts in eastern Canada suggests that a roughly NE – SW compression drives stress perturbation. Under a NE – SW compressive stress regime, Iapetan faults in the CSZ are not optimally-oriented for thrust faulting, and therefore require an additional perturbation of stress orientation to explain the prevalent thrust and reverse – oblique kinematics presently observed. "Weak" faults are a plausible cause for reactivation of non-optimally-oriented faults. Explanations for fault weakening include weak fault materials (clay-rich gauge) (Ikari et al., 2009), dynamic slip weakening and shear heating (Di Toro et al., 2006; Wibberley & Shimamoto, 2005), damage-induced changes in elastic properties (high fracture density) (Faulkner et al., 2006), and elevated pore fluid pressure (Byerlee, 1990).

Previous studies in eastern North America have proposed that postglacial isostatic rebound stresses following the Wisconsin glaciation (85 - 11 kyr) concentrate on faults by localized weaknesses (e.g., dense fracture networks) (e.g., Mazzotti & Townend, 2010; Wu & Hasegawa, 1996). Such stress concentrations on pre-existing zones of weakness may be the most probable source of stress perturbation and driving mechanism of the observed stress rotation. Although the magnitude of post-glacial isostatic rebound stresses are on the order of kPa, localized weaknesses within the highly fractured Charlevoix impact structure may locally enhance stresses. Tarayoun et al. (2018) found that localized structural inheritance amplifies surface strain across St. Lawrence Valley, suggesting that post-glacial isostatic rebound stresses causes significant stress perturbations in structurally weak zones.

The stress orientation observed here (Figure 1b) agrees with previous work. For example, Mazzotti & Townend (2010) found that S_{Hmax} is rotated by up to 47° (when considering the south-eastern cluster) in the CSZ with respect to the borehole breakout measurements. We note that the 64 of the FMS common to this study and Mazzotti & Townend (2010) make up less than 30 % of our dataset, and would unlikely bias our results. Similar clockwise S_{Hmax} rotations of 44° and 49° are reported for the Lower Saint Lawrence Seismic Zone (SLZ) north of the CSZ, respectively, by Mazzotti & Townend (2010) and Plourde & Nedimović (2021). Furthermore, Plourde & Nedimović (2021) also observed a clockwise rotation of ~ 49º of $\sigma_1$with depth in the LSZ, mostly inferred from mid-crustal depths. Similarly, our results show the largest clockwise rotation below ~13 km (Figures 3, and 4), which roughly represents the transition from upper to middle crust in the CSZ (Laske et al., 2013). The pronounced stress rotation observed in both the LSZ and CSZ are consistent with a "weaker" middle crust in both seismic zones. Mazzotti & Townend (2010) also observed that the largest S_{Hmax} rotation inferred from the cluster of events located southeast of the Saint-Laurent fault (Figure S2) relative to the cluster to the northwest. The difference can be explained by the depth-dependent rotation observed in this study, namely, the larger number of shallow events in the northern cluster (0 – 7 km) (Figure S2) results in a smaller stress rotation, whereas the relatively deeper southern cluster reflects the deeper, hence larger stress rotation.

The apparent friction coefficient (μ) calculated by the stress inversion also supports the "weaker" middle crust hypothesis, with highest values of μ (0.65 – 0.8) in the upper crust and lower relative values in the middle crust (0.45 – 0.6) (Figure 3e). A decrease in μ with depth would also explain the decrease in R (Figure 3d). The differential stress ($\sigma_1 - \sigma_3$) for thrust faulting can be expressed as follows (Sibson, 1974):

$$(\sigma_1 - \sigma_3) = (F-1)\, \rho g z\, (1-\lambda)$$

where $F = [(1+\mu^2)^{1/2} + \mu]^2$, ρ is the average crustal density, g is the gravitational acceleration, z is the depth, and $\lambda = P_f/\rho g z$ is the pore fluid factor, with P_f being pore fluid pressure. For thrust faulting $\sigma_3 = (1-\lambda)\, \rho g z$ (vertical stress), and $\sigma_1 = F\sigma_3$ (maximum horizontal stress), making σ_1 dependent on the friction coefficient (μ). Therefore, a decrease in μ will result in a decrease of both $\sigma_1 - \sigma_2$ and $\sigma_1 - \sigma_3$, and a subsequent decrease in R. However, the previous statement is only valid if both σ_2 and σ_3 are not affected by the change of μ.

Similar to the stress inversion results, depth-dependent b-values also show a significant change at the upper – middle crust boundary (12 km - 13 km) (Figure 2d). The b-values clearly decrease with depth until ~12 km and start increasing again following a variable trend. We evaluate possible effects of using M_N in our calculations, and convert M_N to M_W following Bent (2011). Figure S3 shows the M_W depth-dependent b-values follow a similar trend to M_N values (Figure 2). The inverse depth and b-value relationship observed in the upper crust of the CSZ is consistent with of Amitrano (2003) and Spada et al., (2013), both of whom observed decreasing b-values with increasing confining pressure and differential stress. Spada et al. (2013) also suggested that the change in the monotonic trend of *b*-value may reflect the location of the brittle-ductile transition. However, the observed trend reversal in *b*-value at ~ 12.5 km (Figure 2) may not reflect the brittle-ductile transition where seismicity typically diminishes with depth. Rather, seismicity here peaks around 12.5 km and remains abundant down to ~ 22 km (Figure 2a). Therefore, we hypothesize that upper – middle crust boundary located at ~ 12.5 km may instead represent a transition from a brittle behavior of the upper crust to a semi-brittle behavior of the middle crust, where brittle and ductile mechanisms coexist or alternate. The transition to a fully ductile regime likely occurs at ~ 26 km depth at the limit between middle and lower crust (Figure 4).

The discussion in the preceding paragraph accounts for all the events in the catalog. The significantly higher *b*-values between 10 km and 13 km within the impact structure support the presence of a locally highly fractured and weak upper crust (Yu et al., 2016a). The higher local *b*-values are particularly important for probabilistic seismic hazard assessment, given the implications on the frequency of possible future large earthquakes implied by *b*-values. Our results suggest a relatively higher seismic hazard outside the impact structure, when solely based on *b*-values. However, Yu et al. (2016a) interpreted the seismic moment deficit within the impact structure could imply a higher seismic hazard, if the moment deficit is the manifestation of locked faults storing accumulated strain energy. The authors also suggested that aseismic creep and strain release might hinder significant strain energy accumulation. However, the overall low geodetic strain rates in this area (Mazzotti & Adams, 2005; Sella et al., 2007) make it challenging to evaluate which of the above two scenarios is more plausible.

Figure 4 provides a conceptual framework of the crustal rheological structure in the CSZ interpreted from the results of this work. The mostly reverse faulting kinematics inferred from FM solutions in the CSZ (Figure 1b) are consistent with the horizontal compressional stress induced by the postglacial unloading following the Wisconsin glaciation (85 – 11 kyr) (Figure 4b) that is likely amplified by pre-existing structural weakness. The stress inversion results, in particular the depth-variable maximum horizontal stress S_{Hmax}, clearly depict systematic clockwise rotation from the NE-SW orientation inferred from shallow borehole measurements (~ parallel to the St Lawrence River) toward a NW-SE orientation (~ perpendicular to the SLR). The rotated NW-SE S_{Hmax} direction is consistent with maximum strain predicted by Glacial Isostatic Adjustment (GIA) models (Peltier et al., 2015). The largest S_{Hmax} rotation of up to ~ 60° from borehole breakouts is reached at mid-crustal depths ~ 20-26 km, where seismicity ceases. No earthquake FMS are available for stress inversion at greater depth, however, it is plausible that the clockwise rotation continues to approach the GIA estimated strain direction (Figure 4c). The large rotation is possibly due to a significant change in rheological and frictional properties of the middle crust as suggested by the depth-dependent *b*-value and μ variations (Figure 4d). Based on the above interpretations, we hypothesize a rheological profile including a brittle upper crust, a semi-brittle middle crust, and a ductile lower crust (Figure 4d). Finally, the rotation of the σ_1 plunge from near-horizontal (~5°) at the upper crust to shallowly dipping (~15°) at middle crust may reflect the initiation of the gradual transition with depth from a compressional (σ_1 horizontal) to an extensional regime (σ_1 vertical), as is expected under the influence of postglacial rebound (Figure 4a, 4b). Similar to the S_{Hmax} rotation, our stress inversion results can only capture the initial phase of σ_1 plunge rotation (due to the depth limits of seismicity) that likely continues with depth.

Several studies have shown that large earthquakes may produce temporal principal stress rotations in different tectonic settings (Hardebeck & Okada, 2018; Yu et al., 2016b). Here, we use the software Coulomb 3.4 (Toda et al., 2011) to test the extent to which the 1663 M 6+ (Ebel, 2011) event influences the regional stress orientation (Text S3 for details). Our results (Figure S4) show that significant stress rotation occurs within the context of low background differential stress. However, independent of the differential stress, none of the modeled cases explored here accurately represent the present state of stress in the CSZ (Figure 1b). In addition, regional stresses are expected to return to their pre-mainshock orientation within a few months to years (Hardebeck, 2012; Hardebeck & Okada, 2018). Therefore, stress enhancement due to localized weakness, post-glacial isostatic rebound, and ridge-push forces, must be invoked to adequately quantify higher seismic hazard in intraplate seismic zones (e.g., CSZ) in eastern North America.

5. Conclusions

We combine a methodology based on the stress inversion of 225 FMS with the frequency-magnitude distribution properties of earthquakes to investigate the spatial variation of stress field and crustal strength in the CSZ. Our results show that:

- The ~ 40° clockwise rotations of S_{Hmax} obtained from the inversion of the entire FMS catalog supports the hypothesis that pre-existing weaknesses in the CSZ amplify postglacial horizontal stresses.

- The large S_{Hmax} rotation below ~13 km depth is consistent with variable rheological and frictional properties of the middle crust, suggesting low friction coefficient and semi-brittle behavior, which further amplify postglacial rebound stresses.
- The monotonic decrease of *b*-value with depth in the upper ~ 13 km suggest an inverse relationship with differential stress in the upper crust. The relationship becomes insignificant in the middle crust due to its differing rheology.
- Historical large earthquakes do not significantly affect the present-day stress state in the CSZ.

Figure captions

Figure 1. Seismicity in the Charlevoix Seismic Zone (CSZ). (a) Map of relocated earthquakes that occurred between January 1988 and August 2017. Events are color-coded by hypocentral depth. (b) Focal mechanism solutions (FMS) used in this study with the lower-right inset showing the results of the stress inversion from all the FMS. Solid black lines indicate known faults (Lamontagne, 1999; Rondot, 1971). Dashed circles indicate inner and outer boundaries of the meteorite impact structure. Black arrows indicate orientation of maximum horizontal stress from borehole breakouts.

Figure 2. Magnitude-frequency distribution of relocated earthquakes in the CSZ. (a) Distribution of earthquakes with depth. (b) Depth-dependent variation of magnitude of completeness (M_c) calculated using moving windows of 300 events with 150-event overlap. (c) Depth-dependent *b*-value calculated using M_c in (b). (d) Depth-dependent *b*-value variation of using a fixed M_c = 1.86. Black points represent *b*-values for the entire catalog, magenta points indicate *b*-values for

events within the impact structure. Grey bars indicate distribution of $M_N \geq 4$ events in the entire catalog (light) and within the events located inside the impact structure.

Figure 3. Depth-dependent variation of (a) σ_1 azimuth, (b) σ_2 azimuth, (c) σ_1 and σ_2 plunge, (d) stress ratio, and (e) apparent friction coefficient in moving windows of 75 events, overlapping by 15 events. Vertical lines represent depth range of the FMS used in each window, horizontal lines indicate 95% confidence interval. (f) Polar plots of specific stress inversions denoted by numbers (1-3). Black solid lines represent the orientation of the maximum horizontal stress (S_{Hmax}), with black dashed lines indicating 95% confidence interval limits of the. Grey solid lines represent the S_{Hmax} orientation from borehole breakouts (Mazzotti & Townend, 2010).

Figure 4. Schematic NW-SE cross section showing the expected horizontal stress distribution in the lithosphere during (a) glacial loading and (b) postglacial unloading following Wisconsin glaciation (85-11 kyr). (c) Conceptual model showing crustal depth-dependent clockwise rotation of maximum horizontal stress (S_{Hmax}) in the CSZ calculated here (black arrows) compared to S_{Hmax} from borehole breakouts data (grey arrows), and maximum horizontal strain direction from GIA modeling (Peltier et al., 2015). (d) Hypothetical rheological profile of the crust (solid lines color-coded by section of the crust) in the CSZ based on the distribution of earthquakes (grey histogram), *b*-value (dashed red line), apparent friction coefficient (μ) (dashed black line). Black arrows show the calculated rotation of the σ_1 plunge interpreted as possible transition to an extensional regime approaching the neutral plane (a, b). Vertical and horizontal axis do not have the same scale.
