Crustal resistivity structure of the Lunpola basin in central Tibet

and its tectonic implications

Key Points:

- Magnetotelluric data are collected across the Lunpola basin in central Tibet;

- 3-D magnetoteluric inversion result shows the significant low-resistivity mid-to-lower crust beneath the Lunpola basin;

- The less-well-developed weak mid-to-lower crust in central Tibet escapes eastward in a rigid block fashion.

Abstract

In the central Tibetan Plateau, an east-west trending band of basins is developed. How such topography formed and the underlying geodynamic processes are still in debate. Magnetotelluric data were collected across the Lunpola basin to study the crustal structure beneath central Tibet. Phase tensors and 3-D inversion are employed to obtain the electrical resistivity model. Our model clearly portrays conductive sedimentary layers beneath the basins with average resistivity of 2.0 Ω·m. The low-resistivity mid-to-lower crust is revealed beneath the Lunpola basin with bulk resistivity of 20 Ω·m and fluid fraction of 1.3-3.0%, which would be attributed to partial melting. Compared to the significant conductive crust in southern Tibet, the crustal rheology is less well developed beneath central Tibet. We propose that the asthenospheric flow beneath central Tibet is responsible for the crustal partial melting and drives the eastward escape of the continental lithosphere in a rigid block fashion.

Plain Language Summary

The Lunpola basin, belonging to the east-west trending band of basins in the central Tibetan Plateau, records the evolution history of Tibetan Plateau and has good potential in oil and gas resources. Compared to the rugged terrain in southern Tibet, the high-elevation low-relief landform in central Tibet is formed and is less studied. In order to understand the formation of the basins and the underlying geodynamic processes, we utilize magnetotelluric data collected across the Lunpola basin to obtain the deep electrical resistivity structure. The thick sediments beneath the Lunpola basin is clearly imaged with conductive layers. We find that the Lunpola basin has low-resistivity mid-to-lower crust which would be attributed to partial melting. This conductive mid-to-lower crust beneath the central Tibet indicates a less-well-developed rheologically weak state, and is different from the crustal structures beneath the southern Tibet

38 where anomalously conductive layers in mid-to-lower crust are ubiquitously developed.
39 Combined with previous results, we suggest the weak crust beneath the Lunpola basin is blamed
40 for heating from the hot upwelling asthenosphere, and the eastward escape of the wedge basins
41 bounded by conjugate strike-slip faults in central Tibet is driven by the asthenospheric flow in a
42 rigid block fashion.

43

1 Introduction

45   The collision and convergence between the Indian and Asian plates result in the
46 significant N-S shortening, eastward escape and vertical crustal thickening of the Tibetan
47 Plateau, which form largest and highest plateau with abundant active thrust, normal and strike-
48 slip faults on earth (Armijo et al., 1989; Yin et al., 2000, 2011; Tapponnier et al., 2001; Kapp et
49 al., 2005). However, how such topography formed and the crust deformed is still in debate. In
50 central Tibet, an east-west trending band of basins accompanied with a series of V-shaped
51 conjugate strike-slip faults is developed along the Bangong-Nujiang Suture Zone (BNSZ)
52 formed by the Mesozoic collision of the Lhasa and Qiangtang terranes (Yin et al., 2000, 2011;
53 Tapponnier et al., 2001) (Fig.1), and spans most of the interval covering the collision of India
54 and Asia and the resulting tectonic deformation and plateau growth (Rowley and Currie, 2006;
55 Fang et al., 2020; Xiong et al., 2022). Recently, these basins have been the focus to
56 understanding Tibetan elevation evolution and study geodynamic mechanism of the continental
57 deformation (Rowley and Currie, 2006; Wu et al., 2016; Su et al., 2019; Fang et al., 2020; Xiong
58 et al., 2022).

59   The Lunpola basin, one of the several depositional centers in central Tibet, records the
60 most complete Cenozoic sedimentary history (Wu et al., 2016; Su et al., 2019; Fang et al., 2020;
61 Xiong et al., 2022). The palaeo-environment and palaeo-elevation estimations derived from the
62 Lunpola basin support the elevations of central Tibet were generally low (<2.3 km) in the Eocene
63 and became high (>~4 km) since the early Miocene (Su et al., 2019; Fang et al., 2020; Xiong et
64 al., 2022). The formation of the basin would be attributed to the rejuvenation of the BNSZ and
65 the development of the V-shaped conjugate strike-slip faults in response to far-field compression
66 of the India-Asia collision (Kapp et al., 2005; Wang et al., 2014). The central Tibet conjugate
67 strike-slip faults are kinematically linked north trending Tibetan rifts located north and south of
68 the conjugate fault systems. The conjugate strike-slip faults together with the Tibetan rifts
69 facilitate coeval north-south contraction and east-west extension accommodated by the eastward
70 extrusion of a series of small wedges bounded by these conjugate strike-slip faults (Armijo et al.,
71 1989; Tapponnier et al., 2001).

In this study, we mainly used MT data collected along a relatively densely spaced array (~3 km) across the Lunpola basin and nearby area to obtain a 3-D resistivity model for the basin. These MT data allow us to reveal and define crustal structures beneath the basin in central Tibet. From the resistivity model, we analyse and discuss the characteristics of the upper and mid-to-lower crust, calculate the conductance in the depth range of 30-60 km, and alternative geodynamic processes.

2 Regional geological setting

The high-elevation low-relief landform along the BNSZ in central Tibet, extends east-west over a distance of ~1500 km with 20-100 km wide in a north-south direction, including the Gerze Basin in the west, the Bangor, Lunpola, and Nima Basins in the middle and the Dingqing Basin in the east (Fig. 1A). The Lunpola basin is approximately bounded by the Bengco strike-slip fault (BCF) to the south and the BNSZ to the north (Fig.1B). The Lunpola basin contains 4-5 km thick sequences of lacustrine to alluvial sediments, which is believed to have been deposited in a compressional tectonic background initiated in the Late Cretaceous-Early Eocene and reactivated by thrusting in the Early Miocene (Kapp et al., 2005; Wang et al., 2014; Fang et al., 2020). The Cenozoic strata of the Lunpola basin consist of two primary stratigraphic units: the Palaeocene-Oligocene Niubao Formation and the Miocene-Pliocene Dingqing Formation (Rowley and Currie, 2006; Wu et al., 2016; Xiong et al., 2022). The Niubao formation is mainly composed of conglomerates, sandstones, mudstones, marls and tuffs (Wu et al., 2016; Xiong et al., 2022) (Fig. 1B). The Dingqing formation mainly consists of mudstones, shales, sandstones, siltstones and tuffite layers (Wu et al., 2016; Xiong et al., 2022) (Fig. 1B). The depositional ages of the Niubao Formation and the Dingqing Formation are constrained to ~50-29 Ma and ~29-20 Ma respectively (Wang et al., 2014; Wu et al., 2016; Fang et al., 2020).

3 Data acquisition, processing and inversion

3.1 Data acquisition

In 2022, MT data were collected at 23 sites along a nearly N-S transect AA' which is approximately orthogonal to the regional strike of tectonics (red triangles in Fig. 1B). With sites spaced ~3.0 km, the total length of transect AA' was ~70 km. Five components of the time-varying electromagnetic field (Ex, Ey, Hx, Hy, Hz) were measured using commercial Phoenix MTU-5A instruments. The time series were analyzed and processed through robust statistic methods (Egbert, 1997) to estimate MT impedances for the period range of ~0.01-1000 s. Because of sparsely population and poor industries in central Tibet, the quality of the acquired MT data was generally good (Fig. 2). Besides, to the west of the MT profile AA', previous MT data of 9 sites with average ~10 km separation along the profile BB' (blue triangles in Fig. 1B) were supplementary to this study (Liang et al., 2018; Xue et al., 2022).
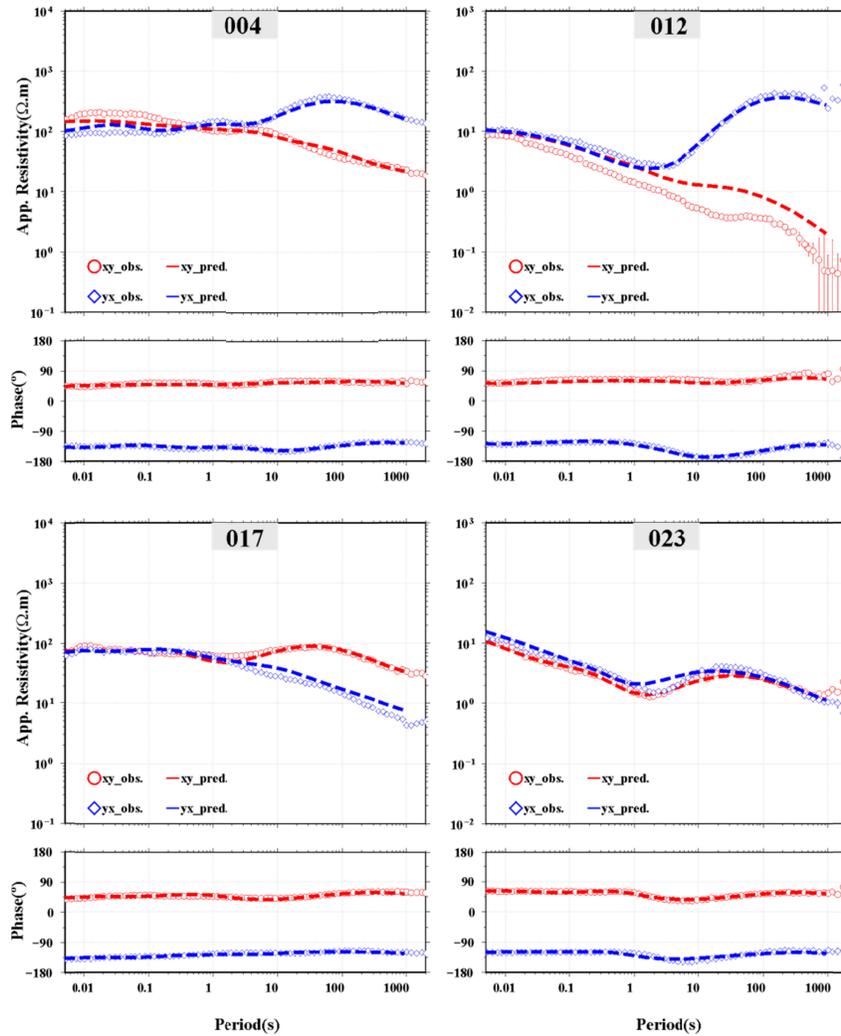

Figure 2. Examples of MT apparent resistivity and phase curves along the profile AA' (locations of sites 004, 012, 017 and 023 are illustrated in Fig. 1b). The red circles and blue rhombuses represent the off-diagonal elements of the impedances. The broken lines (red and blue) show the predicated responses for the preferred model. The error bars are corresponding to the measurement errors of the observed data.

3.2 Phase Tensor analysis

Before the inversion and interpretation of magnetotelluric data are carried out, the phase tensor (PT) decomposition method (Caldwell et al., 2004) is employed to evaluate the dimensionality of the subsurface structure for judging whether a 2D or 3D approach is more appropriate. MT phase tensors are generally expressed as a series of ellipses. The orientations of major axis of the PT ellipses indicate the PT strike direction. The PT skew angle β is represented by the color fills of the ellipse and denotes dimensionality at different periods. Generally, $\beta < 3°$ is required for the data to satisfy 1-D or 2-D assumptions (Booker, 2014; Xue et al., 2021, 2022).
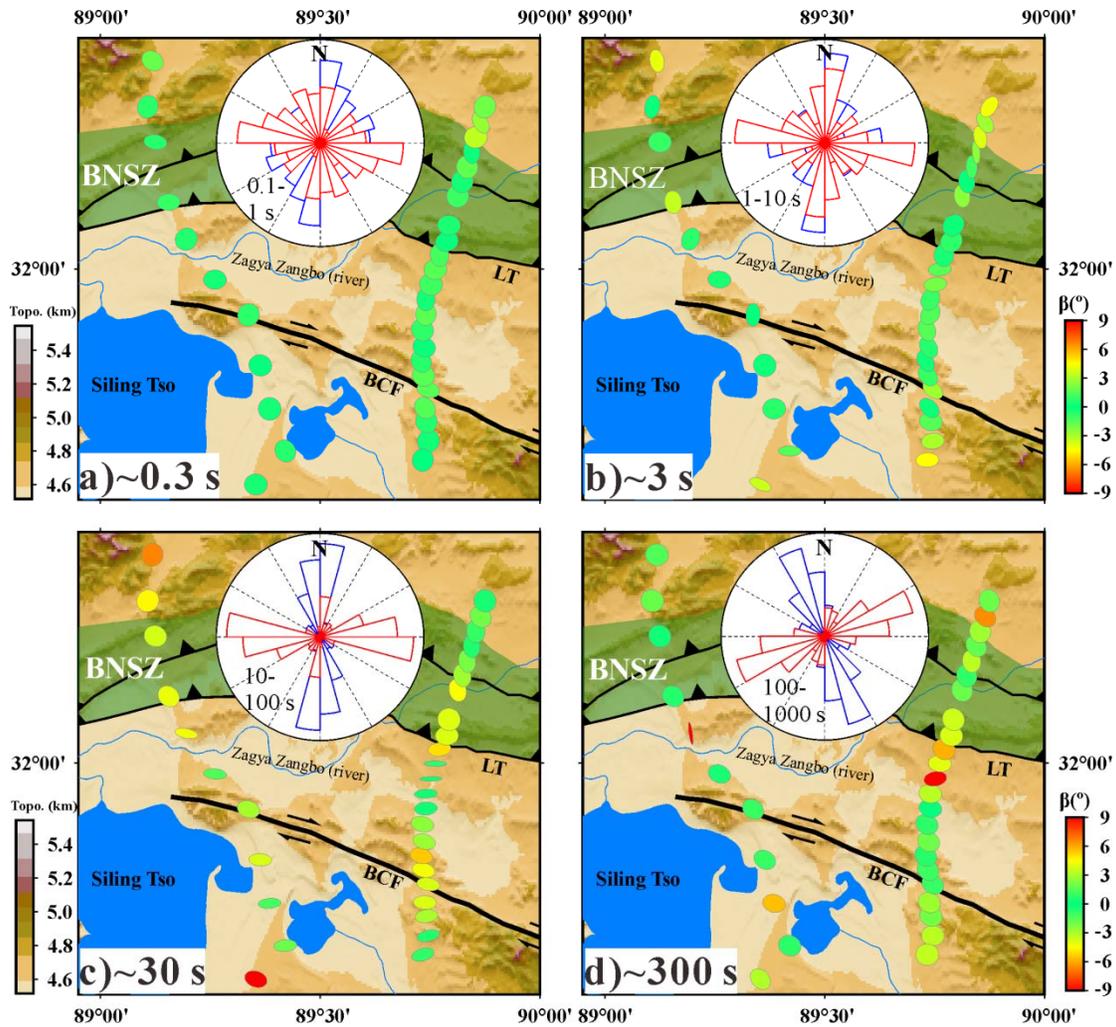

Figure 3. The phase tensor (PT) ellipses for periods: (a) 0.3 s, (b) 3 s, (c) 30 s, (d) 300 s. Rose diagrams show PT strike analysis results for each corresponding period band (0.1-1 s, 1-10 s, 10-100 s, 100-1000 s).

The PT ellipses for each of the 32 sites were plotted in the four periods (~0.3 s, 3.0 s, 30.0 s, 300.0 s) and the rose diagrams of PT strike directions were summarized statistically in the four period bands (0.1-1.0 s, 1.0-10.0 s, 10.0-100.0 s, 100.0-1000.0 s) shown both in Figure 3. At periods 0.3 s and 3.0 s, the PT analysis with small skew angles suggests 1-D or 2D dimensionality at most sites (Fig. 3a and b). The PT strike directions in period bands 0.1-1.0 s and 1.0-10.0 s (Fig. 3a and b) show that a strike direction in the range east to N105°E is the preferred for these data (or orthogonal directions). As period increases to 30.0 s and 300.0 s (Fig. 3c and d), multiple PT skew angles near the BNSZ and BCF rise over 3° without any clear consistent strike directions. For the period band 10.0 -100.0 s, the predominant strike direction clearly lies between east and N105°E with a secondary preferred strike direction between N75°E and east (Fig. 3c). However, the preferred strike direction changes into the range of N60°E-N75°E with a secondary preferred direction between N75°E and east for the period band 100.0-1000.0 s (Fig. 3d). The change in the preferred strike direction is in favor of the existence of 3-D structures. Thus, it's better to employ 3-D MT inversion to obtain effective and reliable crustal electrical resistivity structures.

157
158 3.3 Inversion
159 　　As suggested by the above dimensionality analyses, 3-D modeling and inversion methods
160 are necessary. The 3-D inversion code ModEM (Egbert and Kelbert, 2012) was performed in this
161 study. The full impedance tensors (Z) at 22 equispaced periods in log domain in the range of
162 0.01 s to 1000.0 s were inverted. After 91 iterations, the preferred model was obtained with an
163 overall root-mean-square (RMS) misfit of 1.74. Qualitative comparisons of the fit of the
164 calculated responses to the observed estimates are shown by examining the apparent resistivity
165 and phase curves plotted in Figure 2 and S1. The preferred model in Figure 4 and S2 shows
166 major variations in the resistivity structures in the crust along the profile AA' and BB'
167 respectively. The sensitivity test results (Fig. S3) suggest the MT data could provide effective
168 constrains to the depth of 60 km.

169
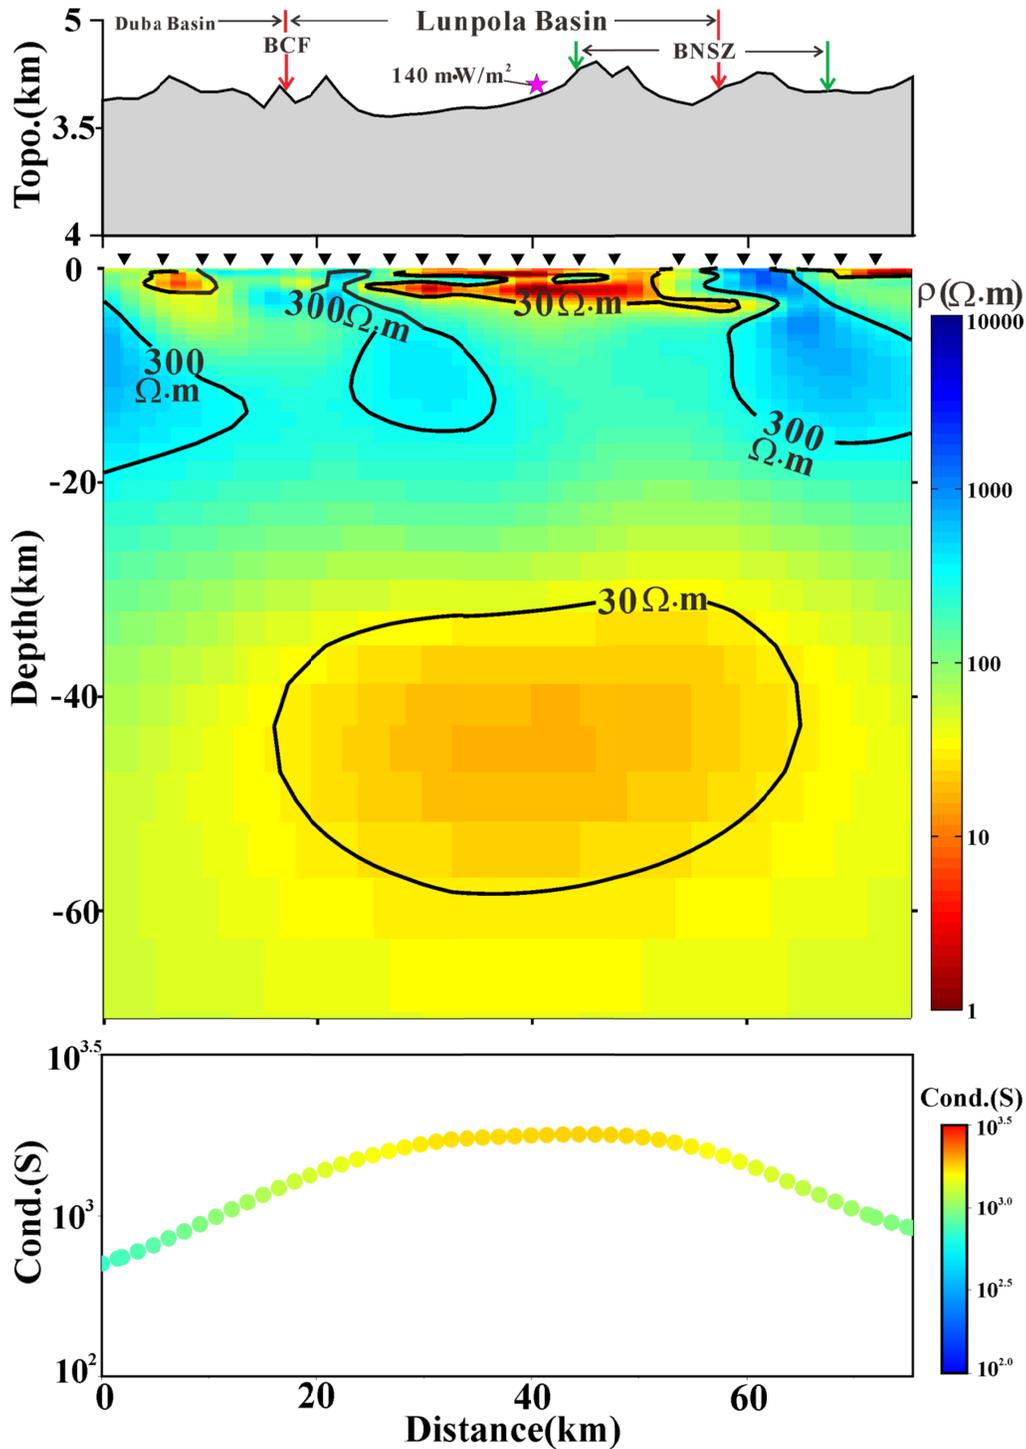

Figure 4. The preferred electrical resistivity model (a) along the profile AA', and the electrical conductance for the depth range of 30-60 km from the preferred model. The magenta star represents the heat flow measurement with 140m·W/m² (Jin et al., 2019).

4 Result and Discussion

4.1 Structure of Upper Crust

175   In the preferred 3-D inversion model (Fig. 4 and S2), the first-order electrical structures
176 along the N-S profile are mainly composed of two contrasting layers that the resistive upper crust
177 ($\leq$ ~20 km) is underlain by the significantly low-resistivity middle and lower crust (~30-60 km).
178 Within the upper crust, three prominent conductive zones (Fig. 4) are observed near the surface,
179 which correlate spatially with the Duba basin at the southern transect, Lunpola basin in the
180 central and topographic depression at the northern end, respectively. These discrete conductors in
181 the upper crust are also observed in the previous results of the neighboring regions (Wei et al.,
182 2001; Solon et al., 2005), and are confined to the low-velocity surficial layer defined in the wide-
183 angle experiment (Zhao et al., 2001). Beneath the conductive surface layer, resistivities increase
184 rapidly to hundreds of ohm meters.

185   The conductive surface zones are commonly believed to be associated with Mesozoic
186 basin sediments overlain by Tertiary cover (Solon et al., 2005; Heinson et al., 2006). It's
187 reasonable that the enhanced porosity of the basin should increase its conductivity, and resistivity
188 variations within the sediments along the profile would be attributed to porosity differences and
189 rock mineral compositions (Unsworth et al., 2004; Solon et al., 2005; Heinson et al., 2006).
190 Beneath the Lunpola basin and nearby basins, the Cenozoic cover with low resistivities of 1-30
191 Ω·m is at least about 5000 m thick in a depocenter, which are in accord with the geological and
192 drilling data (Wu et al., 2016). When the subsurface fluids (aqueous fluid or partial melting)
193 form a well interconnected network and significantly decrease the resistivity, the content of deep
194 fluids can be quantitatively estimated using the Archie's law (Unsworth et al., 2004, 2005; Bai et
195 al., 2010; Dong et al., 2020). In the center of the Lunpola basin, the saline fluid fraction of 7.4-
196 16.8% can explain the average sedimentary resistivity of about 2.0 Ω·m (Fig. S4).

197

198 4.2 Mid-to-lower Crustal Feature

199   In the preferred model (Fig. 4 and S2), the dominant feature is the conductive mid-to-
200 lower crust. The sensitivity test shows the conductive anomaly in the middle and lower crust is
201 robust (Fig. S3). We integrate the conductivities with depth to obtain conductance for the depth
202 range of 20-60 km from the preferred model (Fig. 4B). The maximum conductance is about 2000
203 S beneath the Lunpola basin and the bulk resistivity is 20 Ω·m. As the anomalously low
204 resistivity of the mid-to-lower crust in Tibet is a ubiquitous phenomenon which transect the
205 whole plateau and its periphery (Wei et al., 2001; Solon et al., 2005; Unsworth et al., 2004, 2005;
206 Dong et al., 2020; Xue et al., 2021), we believe the conductive anomaly in middle and lower
207 crust beneath our profile must be the result of interconnected melt and/or aqueous fluids
208 developed during the plateau's evolution. Using the Archie's law, the melt fraction is estimated
209 in the range 1.3-3.0% for the bulk resistivity of 20 Ω·m beneath the Lunpola basin (Fig. S4).

210   In southern Tibet anatectic crustal melts and metamorphic brines generated as a
211 consequence of underthrusting Indian crust and crustal thickening are the most likely candidates
212 (Nabelek et al., 2009; Dong et al., 2020; Xue et al., 2021). However the northern limit of the
213 underplated crust of the Indian plate is approximately parallel to about 30°N (Li et al., 2008;
214 Nabelek et al., 2009; Xue et al., 2021) which is far away from the Lunpola Basin. In northern
215 Tibet, the upper mantle is characterized by inefficient S-wave (Sn) propagation, low P-wave (Pn)
216 velocity and strongly developed shear-wave anisotropy which indicates a hot anomalous mantle
217 (Huang et al., 2000; Owens and Zandt, 1997). The partially melted mid-to-lower crust beneath
218 the northern plateau is suggested be attributed to high temperatures (Owens and Zandt, 1997;
219 Solon et al., 2005). The influx of heat from the hot underlying upper mantle or mantle derived
220 melts injecting into the lower crust is a major influence on the development of this anomalous

221 crustal structure (Owens and Zandt, 1997; Huang et al., 2000; Solon et al., 2005). The Lunpola
222 basin is within or near the southernmost edge of a region of high Sn attenuation and low upper
223 mantle velocities. Therefore the hot upper mantle is suggested to blame for the partially melted
224 mid-to-lower crust beneath the Lunpola basin. The high heat flow (140 m·W/m^2) (Fig. 1 and 4)
225 (Jin et al., 2019) measured in the Lunpola basin favors the presence of the hot resource.
226   Compared to high electrical conductivities (~0.3 S/m) in mid-to-lower crust in the
227 southern Tibet (Unsworth et al., 2005; Chen et al., 2018; Xue et al., 2021, 2022), the bulk
228 conductivity (0.05 S/m) in mid-to-lower crust beneath the Lunpola baisn is clearly lower and
229 analogous to the observed conductivities (~0.067 S/m) near the Karakorum strike-slip fault zone
230 in the north-western Himalaya (Unsworth et al., 2005; Arora et al., 2007; Chen et al., 2018). The
231 bulk conductivity of ~0.3 S/m requires a melt fraction of 5-14% which is sufficient to produce an
232 order-of-magnitude reduction in viscosity, while the bulk conductivity of ~0.05-0.067 S/m
233 requires a melt fraction of 1.3-4% that correspond to a more modest reduction in viscosity and a
234 less-well-developed crustal flow (Unsworth et al., 2005). Chen et al. (2018) suggested the
235 variation in bulk conductivity and melt fraction beneath the north-western Himalaya and the
236 southern Tibet is attributed to fluid-absent melting and fluid-present melting respectively. The
237 fluid-absent melting in mid-to-lower crust beneath the Lunpola basin in turn demonstrates the
238 termination of the northward underthrusting Indian crust near 30°N (Li et al., 2008; Nabelek et
239 al., 2009; Xue et al., 2021) which can provide sufficient fluids. Besides, the changes in crustal
240 resistivity from south to north are also consistent with the changes in crustal velocity and
241 Poisson's ratios which may be associated with the differences in upper-mantle structure and
242 properties (Owen and Zandt, 1997; Huang et al., 2000).
243
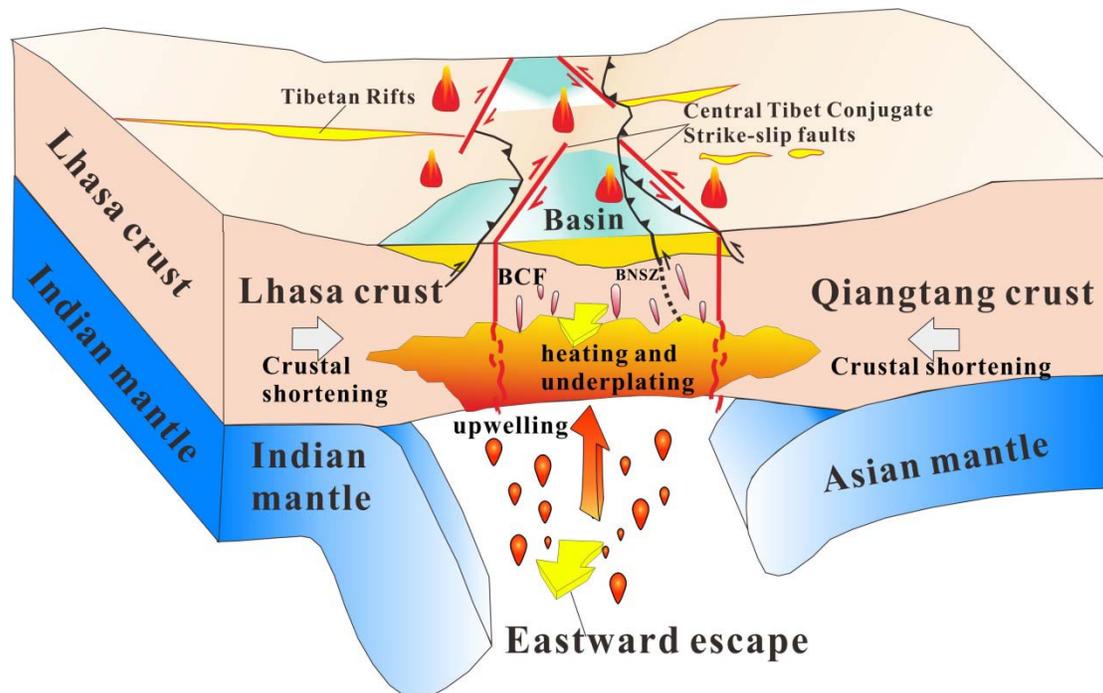

244
245 Figure 5 Interpretive cartoon illustrating the crustal deformation and underlying geodynamic processes beneath
246 the central Tibet. Underthrusting of the Indian and Asian mantle lithosphere caused north-south contraction of
247 the hot and softer asthenospheric channel, resulting in eastward asthenospheric flow and upwelling. Horizontal
248 shear applied at the base could have driven the eastward escape of the central Tibet. The asthenospheric
249 upwelling could induce basaltic underplating and thermally weaken the crust.

250
251 4.3 Eastward Escape of central Tibet
252   For the crustal deformation mechanisms and geodynamic processes in the central part of
253 the Tibetan Plateau, Yin and Taylor (2011) proposed that the eastward asthenospheric flow along
254 the BNSZ sandwiched between the cold Indian and Asian lithosphere applies horizontal shear at
255 the base of the Tibetan mantle lithosphere to drive Cenozoic deformation of central Tibet.
256 Recently based on paleotemperatures from the Lunpola Baisn, Xiong et al. (2022) proposed that
257 mantle upwelling, immediate basaltic underplating and crustal shortening together contributed to
258 the rise of the central Tibetan Valley. A number of evidences support a hot upper mantle in
259 central Tibet and vertically coherent deformation of lithosphere of central Tibet (Owens and
260 Zandt, 1997; Huang et al., 2000; Yin and Taylor, 2011). As discussed in section 4.2, the heating
261 effect from the hot mantle would thermally weaken the crust characterized by low-resistivity
262 anomalies (Fig. 4) and promote the crustal deformation. Nevertheless the relatively weak mid-to-
263 lower crust beneath the Lunpola Basin is not enough to decouple the upper crust from the lower
264 crust and the mantle lithosphere, which supports the crust and mantle lithosphere are deformed in
265 a coherent fashion.
266   Our concept of the geodynamic processes driving late Cenozoic deformation of central
267 Tibet is summarized in Fig. 5. In the model, underthrusting of the Indian and Asian mantle
268 lithosphere caused north-south contraction of the hot and softer asthenospheric channel, resulting
269 in eastward asthenospheric flow and upwelling. The basal shear at the base of the Tibetan
270 lithosphere due to the asthenospheric flow, induces lateral motion of regional portions of the
271 continental lithosphere bounded by conjugate strike-slip faults in central Tibet in a rigid block
272 fashion (Yin and Taylor, 2011). Meanwhile, the asthenospheric upwelling could contribute to
273 basaltic underplating and thermally weakening the crust, which promote crustal shortening and
274 deformation, and rapid surface uplift of the central Tibet (Xiong et al., 2022).
275

5 Conclusions

277   In central Tibet, a series of Cenozoic basins along the Bangong-Nujiang suture are formed,
278 and record the tectonic deformation and plateau growth responding to the collision of India and
279 Asia. To study how the basins formed and the underlying geodynamic processes, magnetotelluric
280 data across the Lunpola basin were collected to reveal the crustal structures beneath the basin
281 and nearby area. Phase tensor analysis and 3-D inversions are performed to obtain the electrical
282 resistivity model. The preferred model shows that the resistive upper crust inlaid with three
283 surface conductive zones, is underlain by the significantly conductive middle and lower crust.
284 The surface conductive zones correlate spatially with the basins and indicate the thick
285 sedimentary sequences. The low-resistivity mid-to-lower crust is believed to be the result of
286 partial melting, which may be attributed to fluid-absent melting induced by heat from the hot
287 underlying upper mantle. The maximum conductance for the mid-to-lower is 2000 S with the
288 bulk resistivity of 20 $\Omega \cdot$m, and the estimated fluid fraction is 1.3-3.0%. Compared to the
289 significant weak mid-to-lower crust in southern Tibet, the crustal rheology is less well developed
290 beneath central Tibet and not enough to decouple vertically from the mantle lithosphere.
291 Combined with the previous studies in central Tibet, we suggest the crust and the mantle
292 lithosphere are deformed in a coherent fashion, and propose that the hot asthenosphere beneath
293 the central Tibet sandwiched between the cold Indian and Asian lithosphere, is squeezed to flow

294 eastward and upwells, resulting in the relatively weak mid-to-lower crust and driving the
295 eastward escape of the continental lithosphere in central Tibet.

Data Availability Statement

305 Inversion data files for the Magnetotelluric array study on the deep geo-electrical and
306 rheological structure of the crust structure underneath the Lunpola basin beneath the central
307 Tibet, was conducted by Institute of Geology, Chinese Academy of Geological Sciences in
308 Beijing. The inversion data sets including the Magnetotelluric data and the model file used in this
309 study are temporarily available in the "Data File(s) for Peer Review." If the paper is accepted for
310 publication, the data will be archived at a FAIR compliant repository. The Kelbert et al., 2014
311 paper (https://doi.org/10.1016/j.cageo.2014.01.010) are recommended to refer for a brief
312 understanding of the model and transfer function data file formats.
